## Climatic Normals as Predictors, Part 5: Conclusion

### FINAL REPORT

#### ABSTRACT

Methods of previous Reports, concerned with the number of antecedent years for which the mean value of a climatic element offers the minimum variance estimator of the next year's value, are extended to similar predictions more than one year ahead. For predicting a value  $m$  years beyond the end of the averaging period, the best average is found to be based on a period  $m$  years shorter than for predicting the next year's value. Apparently each climatic record has an average period of maximum homogeneity, whose length must be equalled, for optimum prediction, by the interval from the start of the averaging period to the end of the predicted one. Climatic normals for 15-year periods, rather than 30 years as at present, are recommended, with recomputation every 5 years. Medians of values over 15 years are suggested as even better predictors than means. Finally, 7 years is suggested as a suitable period for the definition of climate.

## Climatic Normals as Predictors, Part 5: Conclusion

FINAL REPORT1. Introduction

Prediction, rather than description, is the primary purpose of weather observations, whether assembled for synoptic analysis or tabulated into climatic summaries. While the avowed intent of a climatic summary may be to "describe" climate, any description of past conditions is of little value unless persistence is assumed. The overwhelming use of climatic statistics is for the estimation of future conditions: the clothes needed for a trip, the size of the furnace for a new building, the crops that can be introduced into a region, the most advantageous route for an airplane, and so on.

In summarizing their statistics, however, few climatologists consider the uses to which the results will be put. They follow faithfully the 19th century criteria for characterising climate, although granting grudgingly the fallacy of the concomitant concept of climatic constancy. Climatology is far more persistent than is climate.

Climatic "normals," cornerstones of climatology, are senescent survivors of the pervasive proposition of permanency. Until the last century, hills were everlasting, biologic species had not changed since Creation, and "climate" was the fixed value about which weather conditions varied randomly. The accepted characteristics of a species were averages of many measurements of individual eagles or eels or elephants, and the "true" climate was the average of weather observations for many years, the more the better.

With the slow acceptance, in this century, of the reality of climatic changes and fluctuations, the 19th century description of a place's climate by the average of all available observations, regardless of when made, has been replaced by a rigid recipe: the mean of observations during a period of 30 consecutive years, beginning in 1901, 1931, 1961, etc. A period of 30 years, rather than 10 or 25 or 50, apparently was chosen

(by the International Meteorological Organization in 1937) as the shortest period for which an average would be meaningful or stable. The variance of the average of  $k$  independent observations from a normally-distributed population is  $1/k$  times the variance of the individual observations, so the standard error of a 30-year mean would be  $30^{-1/2} = 0.18$  times the standard error of each observation.

The presumed precision of a climatic quantity, however, has much less intrinsic importance than the expected error with which it forecasts future phenomena. For what period should a climatic "normal" be computed so as to approximate most closely coming conditions? This question, little investigated previously, is discussed in the present Report, the result of almost three years of study.

Various aspects of this question have been discussed in four previous Scientific Reports. SR 1 examined, in greater detail than here, the history and definition of climatic normals, and summarized and compared five previous studies, in the U.S., England, and Russia, on the number of years for which the average offered the best estimate of the following year's temperature, precipitation, or streamflow. SR 2 extended these analyses, in greater detail, to monthly temperature and precipitation at 7 U.S. stations, verifying the findings of previous authors that, in general, means based on anything more than 10 years were about equal in predictive precision. SR 3 showed that the next year's value was slightly closer, on the average, to the median of the antecedent values than to their mean. SR 4 verified the results of the previous authors, and of SR 2, for a variety of U.S. and foreign records of temperature, precipitation, rainy days, and sunshine percentage.

The present Report offers the somewhat surprising results of seeking the period for which the mean (or median) estimates most closely a value more than one year beyond the end of the period. It also presents the conclusions of the entire study, quite different from those anticipated when it began. An appendix contains translations of two Russian papers, already discussed in SR 1.

## 2. Methodology

Throughout this study, the primary interest has been in defining the number of years,  $k^*$  ("k-star"), over which a moving average gives the "best" estimator of an average for the  $\lambda$  years beginning in the  $k + m$ th year:

$$\begin{array}{ccccccc} & & k & & \text{---}m\text{---} & & \lambda \\ & & \text{-----} & & \text{-----} & & \text{-----} \\ i = & 1 & 2 & 3 & \dots & \dots & n \end{array}$$

In all except one of the previous studies, and in SR 2 and SR 4, the criterion of "best" was taken to be minimum variance. The desired  $k^*$  was the value minimizing

$$S_{k\lambda m}^2 = \frac{1}{n-k-\lambda-m+2} \sum_{i=1}^{n-k-\lambda-m+2} \left[ \frac{1}{\lambda} \sum_{j=m}^{m+\lambda-1} x_{i+j+k-1} - \frac{1}{k} \sum_{j=0}^{k-1} x_{i+j} \right]^2$$

One previous study used mean absolute error, obtained by taking the absolute value, rather than the square, of the difference, and here designated as  $Q_{k\lambda m}$ . This criterion was also applied in SR 2, and used in SR 3 for comparison with the mean absolute difference between the median of the antecedent years and the next year's observation; in this study this quantity is designated as  $D_{k\lambda m}$ .

In all previous studies, except for portions of two, and in SR 2, SR 3, and SR 4, the  $k$ -year means (or medians) were compared only to the next  $(k + 1)$ st value, i.e. both  $\lambda$  and  $m$  were one. (Actually,  $m = 1$  means that no intervening observation is omitted.) As mentioned in SR 2, and given in detail in SR 3, the FORTRAN IV program developed for the present study computes  $S_{k\lambda m}^2$ ,  $Q_{k\lambda m}$ , and  $D_{k\lambda m}$  for  $\lambda = 1$  with  $m = 1, 2, 3, \dots, 10$ , and for  $\lambda = 10$  with  $m = 1$ . Complete results were printed out in a table in which successive lines give  $S_{k\lambda m}^2$  for  $k = 1, 2, 3, \dots, 50$  or  $Q_{k\lambda m}$  or  $D_{k\lambda m}$  for  $k = 1, 3, 5, \dots, 49$ . Successive columns are for  $m = 1, 2, 3, \dots, 10$  with  $\lambda = 1$ ; the final column gives values for  $\lambda = 10$  and  $m = 1$ , for

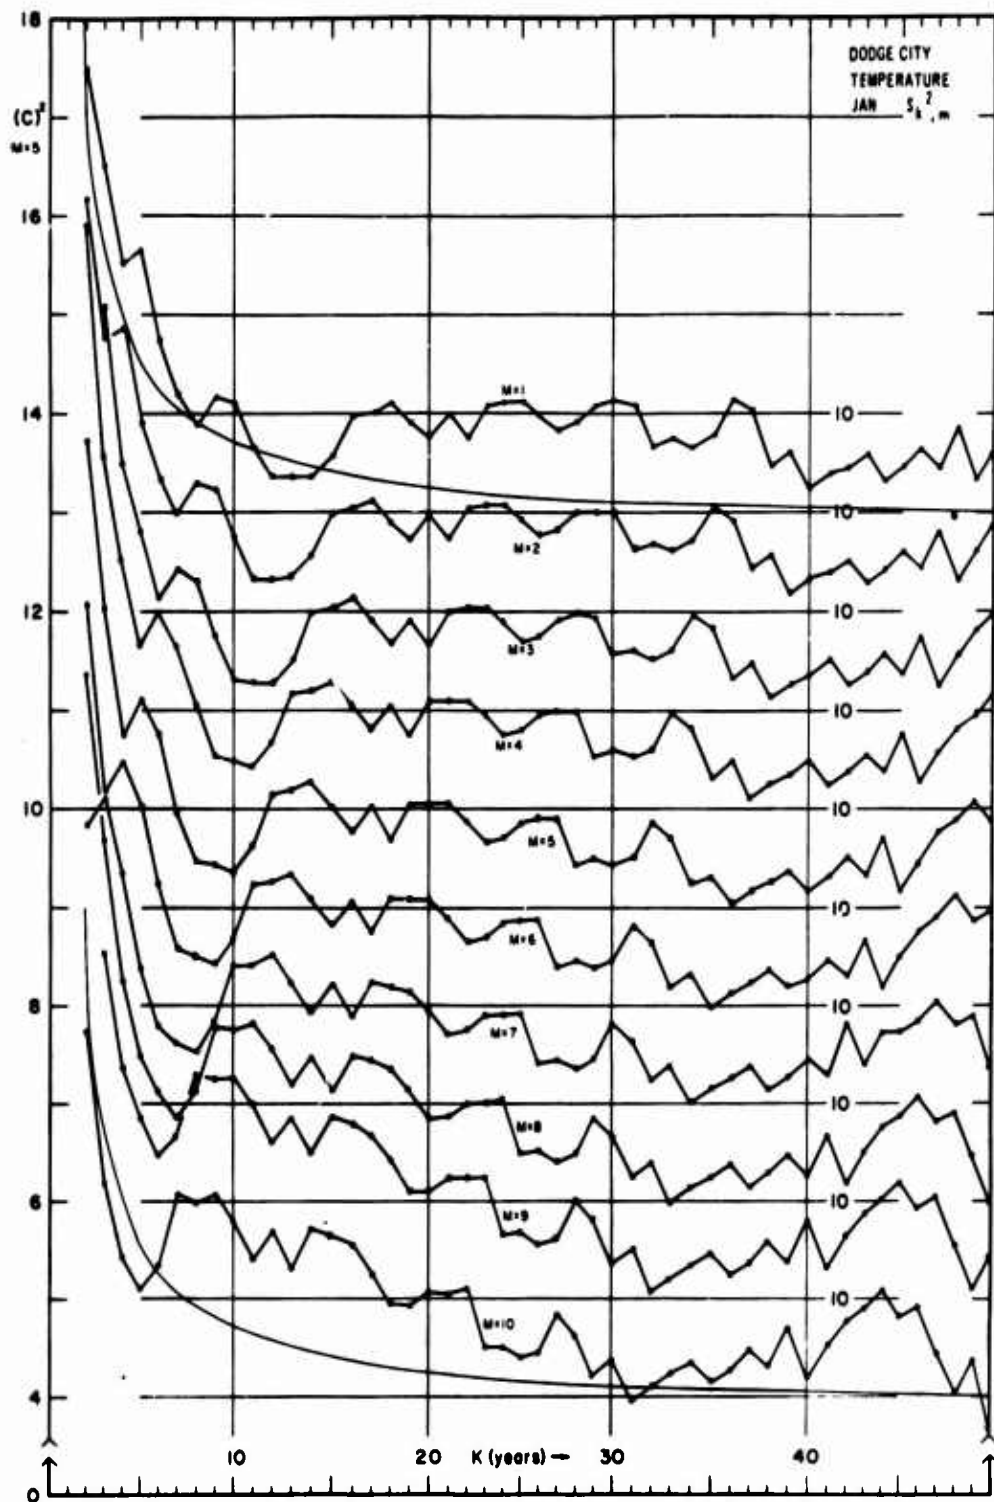

Figure 1.  $S_{k/m}^2$  as a function of  $k$  for  $m = 1, 2, \dots, 10$ ,  
for January temperatures at Dodge City, Kansas,  
1874-1960

predicting the mean over the 10 years immediately following the  $k$  years. The complete program, with examples of the printout, is given in SR 3.

For each variable in each month at each station, therefore, six full pages of printout were received, with the input data on a seventh page. The many figures of SR 2 and SR 4 summarize the results of only the first columns of the tables.

Representation similar to those of SR 2 and SR 4, but for all 10 values of  $m$ , is offered in Figure 1, for January temperatures (1874-1960) at Dodge City, Kansas. Shown are curves of  $S_{k/m}^2$  as a function of  $k$ , separately for each  $m$ . The topmost curve is the January curve of Figure 1B in SR 2. Below it, for increasing lags,  $m$ , are the corresponding curves, each displaced downward by one unit. Each curve varies generally between 8 and 12 deg<sup>2</sup>, around a line labelled "10". The ordinate is labelled for the topmost curve, and is interrupted near the bottom so that all curves could be shown on a single sheet. The bottom curve, for  $m = 10$ , represents the extrapolation variance when a  $k$ -year mean is used to predict the January temperature 10 years after the end of the  $k$ -year period.

### 3. Discussion

The most unexpected, and most significant, result of the entire study is shown clearly in Figure 1, and would be just as clear in a similar figure for any of the other computations. The curves are very similar in shape, but for each additional year of extrapolation, they shift one year to the left, toward smaller values of  $k$ . In this example,  $k^*$  is 40 years for prediction one year ahead, 39 years for two years ahead, and so on to 31 years for predicting the temperature 10 years ahead.

This behavior was apparent on almost all the printout sheets, on which the minimum value of  $S_{k/m}^2$  in each column, which identified its  $k^*$ , was marked by an asterisk, as shown in the tables in SR 3. These asterisks "marched uphill" on most of the tables. In addition, secondary minima behaved similarly, as shown by the first major dip in the curves of

Figure 1, which begins at  $k = 12-14$  for  $m = 1$  and regresses to  $k = 5$  for  $m = 10$ .

To represent the behavior of  $S_{k/m}^2$  as both  $k$  and  $m$  vary, with  $\lambda = 1$ , isopleths of the values on the computer printout sheets were drawn on overlays. Examples are shown in Figure 2, for annual precipitation and temperature at Dodge City. On each diagram, dots mark the value of  $k^*$  for each  $m$ . The isopleths indicate the values of  $S_{k/m}^2$ , in  $\text{deg}^2$  for temperature and  $\text{cm}^2$  for precipitation.

In the left-hand diagram, for precipitation, two general troughs of minimum values are shown, both trending upward, to decreasing values of  $k$  with increasing  $m$ . Most  $k^*$  dots fall in the lower trough, but three occur in the upper one. In the right-hand diagram, for temperature, the isopleth pattern is less marked, but the  $k^*$  dots trend generally upward until, at  $m = 8$ , they drop to a second trough and then resume the upward march.

Similar diagrams for annual temperature and precipitation at the other six stations are shown in Figures 3 and 4. On both, the general trend of the patterns is toward smaller values of  $k$  as  $m$  increases, and the  $k^*$  dots show the same trend, unexpected and at first quite mystifying. Only at Lynchburg, for both elements, is the pattern at all unclear, but it still is not markedly different from the others.

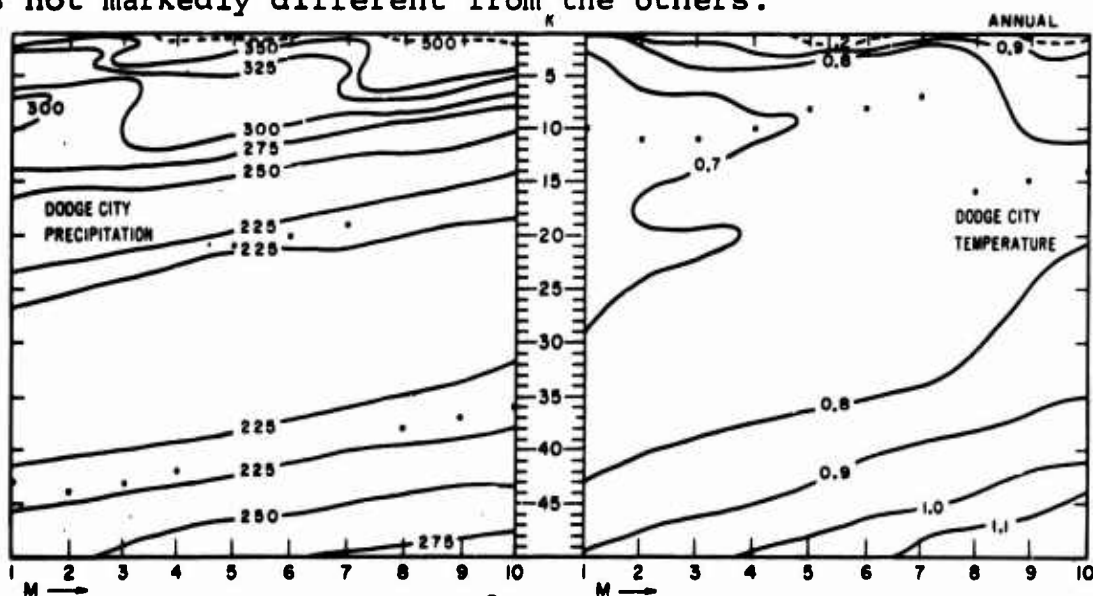

Figure 2. Isopleths of  $S_{k/m}^2$  for annual precipitation and temperature at Dodge City, Kansas, 1874-1960.

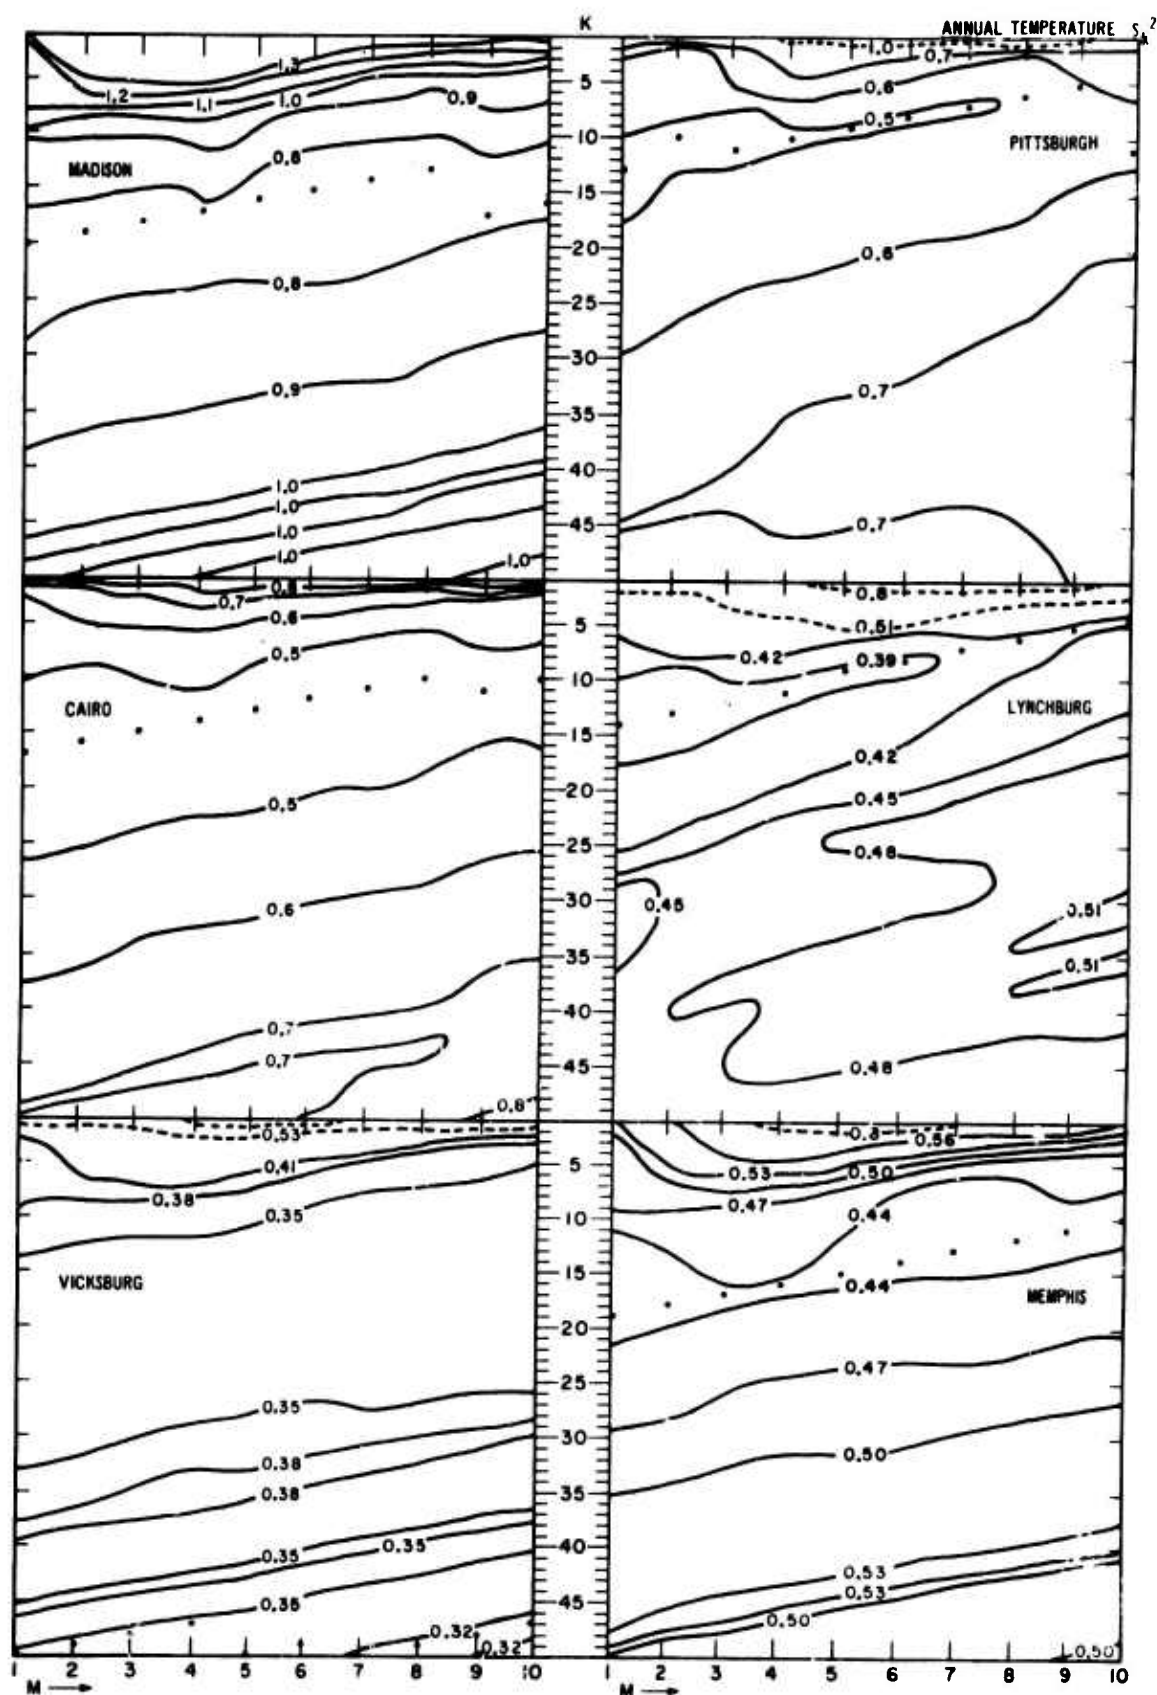

Figure 3. Iospleths of  $S_{k\lambda}^2$  for annual temperature  
at seven U. S. stations

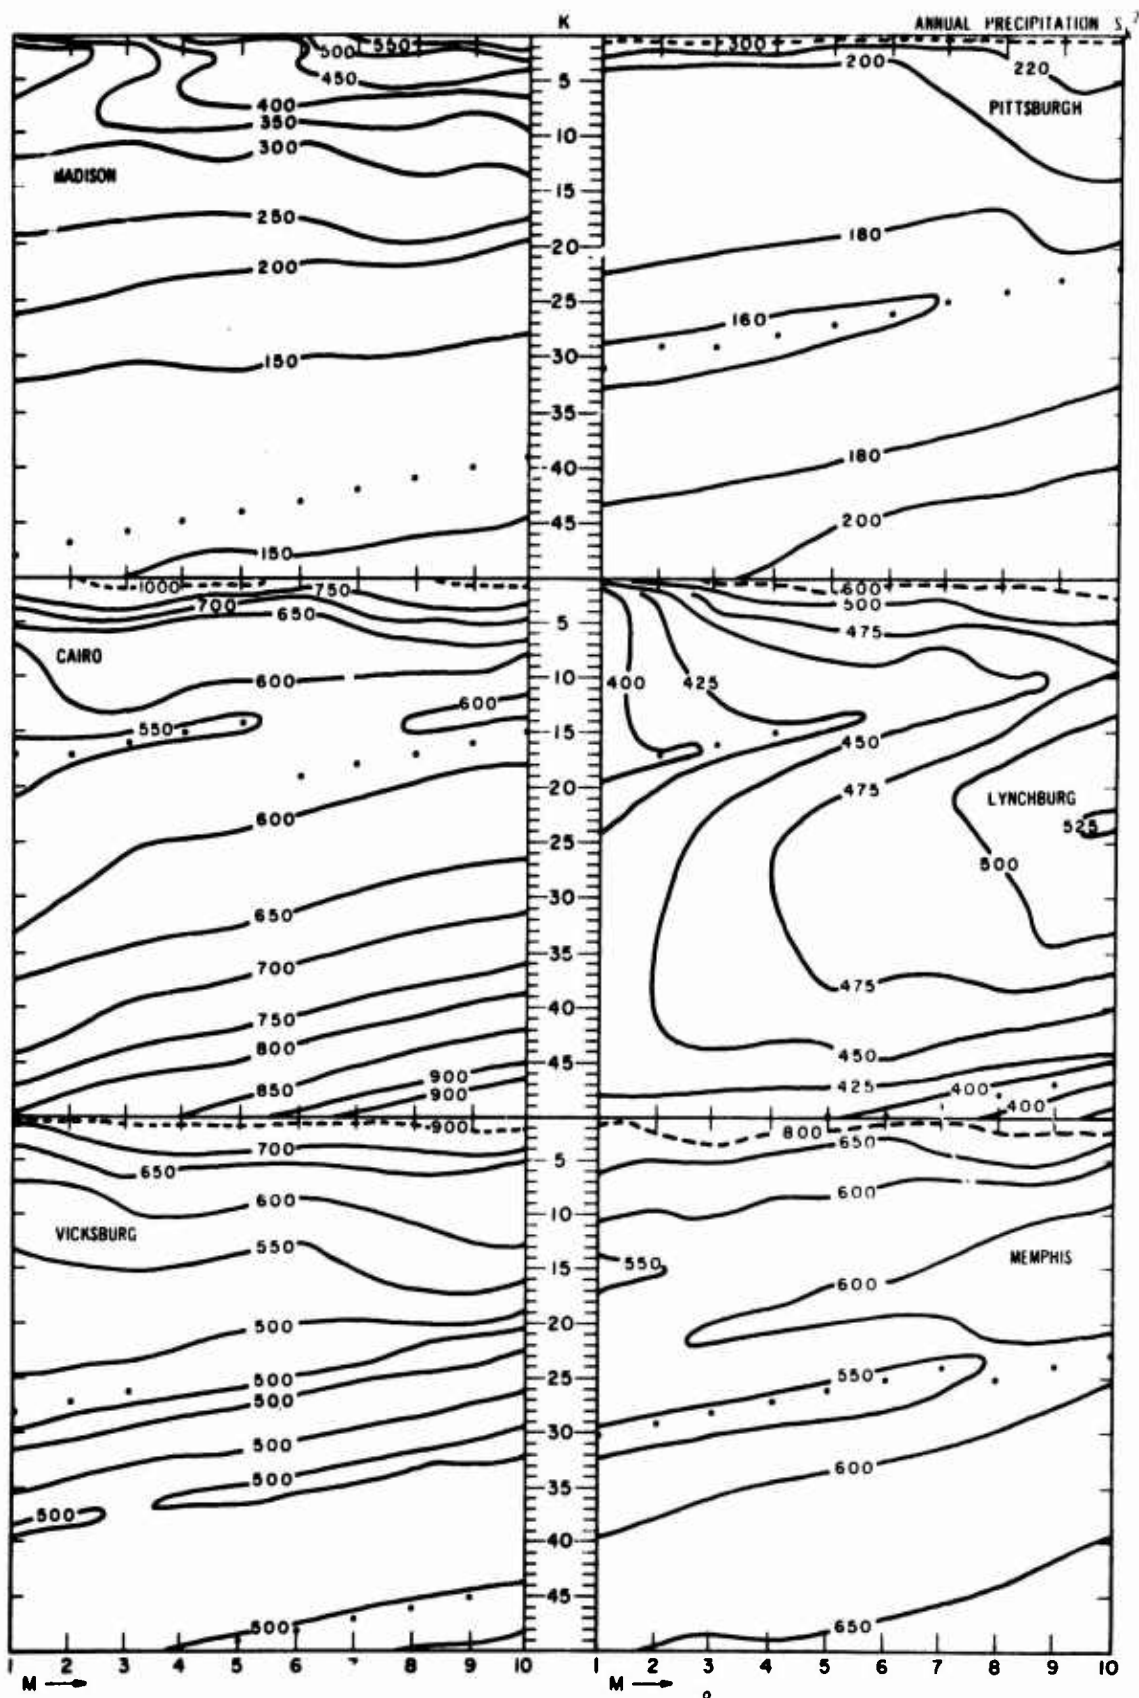

Figure 4. Iospleths of  $S_{k\lambda}^2$  for annual precipitation  
at seven U. S. Stations

unexpected and at first quite mystifying. Only at Lynchburg, for both elements, is the pattern at all unclear, but it still is not markedly different from the others.

The monthly diagrams (Figures 5 to 10 for temperature, 11 to 16 for precipitation) show this same characteristic. It also appears on the printout sheets for all the other places and elements considered in SR 2 and SR 4. Although the actual value of  $k^*$  may vary markedly from month to month and element to element, it is usually one year less for each additional year of extrapolation.

#### 4. Explanation

Why should the temperature, precipitation, or sunshine in the year after next be estimated best by the mean (or median) of an antecedent period one year shorter than that appropriate for next year's value? The exact opposite relation had been conjectured at the start of the study: the original hypothesis was that the optimum length of antecedent record would be directly proportional to the length to which it would be extrapolated. If next year's value was best estimated by the mean (or median) of the preceding 20 years, a value 10 years ahead was assumed to require a somewhat longer antecedent period. This conjecture was incontrovertably refuted by many computations, a few of which are summarized diagrammatically in the figures included here.

Any valid explanation of this inherent characteristic of climatic series must be also compatible with concurrent conclusions of this study. As developed in SR 2 and SR 4, these are generally that, for prediction purposes, each climatic element behaves differently in each month at each station, but may have some regional resemblances in some months. The erratic behavior of  $S^2$ ,  $Q$ , and  $D$  represents the inherent variability of weather and climate, and is not the result of observational practices.

No significant serial correlation has been found for annual or monthly values of climatic elements. However, smoothing such correlations by a Fourier transform into a power spectrum

shows supposed significant spectral spikes. For example, in the Woodstock data, presented in SR 4, Landsberg, Mitchell, and Crutcher (Mon. Wea. Rev. 87:283-298, 1959) found that "Spectral peaks in temperature, of periods near 2 years and greater than 50 years, both achieve high levels of statistical significance."

Spectrum analysis, however, can apply only to the past record, and no procedures are available to establish the persistence into the future of any apparently significant peaks. When long series of observations are divided into segments, each sufficiently long for spectrum analysis, results often differ for the various segments. Similar differences were found for extrapolation variance in the two halves of the long temperature series at Hohenpeissenberg, Basel, and Geneva (SR 4). Hence the results of any spectrum analysis of climatic data cannot validly be extended to the future.

Nevertheless, some light serial dependence may be present in climatic elements. If they were completely random,  $S_k^2$  would decrease generally according to  $1 + 1/k$ . Many  $S_k^2$  curves, however, wander up and down, in a manner similar to curves for random normal variables biased in mean or in variance (SR 1).

Essentially, monthly and annual means of climatic elements behave like a stochastic process which is non-stationary in mean and variance. Alternatively, the observations may be considered as drawn from two or more different populations, each with constant mean and variance, but with the mixing ratio variable in time. This hypothesis has been considered, in various ways, by many investigators.

Climatic records can be described, and hence considered to be explained by either of these models, or even both. But such explanation has the same limitation as any other analytic description of climate: it does not lead to useful prediction. No procedures are available for estimating future values of means, variances, or mixing ratios. In the present study, efforts were made to use each of these models, but were abandoned when this inherent non-predictability became apparent.

## 5. Conclusion

Whatever the probabilistic nature of climatic elements, any long series of their monthly and annual values has an average period of maximum homogeneity or minimum variability of  $h$  years. In such a record, therefore, the average difference between means over two disjoint intervals, of  $k$  and  $\lambda$  years, separated by  $m$  years, is least when

$$k + m + \lambda = h - 1 .$$

This average interval of maximum homogeneity is  $h = k_{1,1}^* + 1$  when  $k_{1,1}^*$  is the length of antecedent period for which the mean provides the minimum variance estimator of the  $k + 1$ st value, i. e. with  $\lambda = m = 1$ . As the extrapolation interval,  $m$ , increases, the corresponding  $k_{\lambda m}^*$  must decrease. As the prediction interval,  $\lambda$ , increases,  $k_{\lambda m}^*$  also decreases.

This explanation is the only rational conclusion that can be drawn from the evidence, in previous Sections of this Report, that  $k^*$  decreases directly as  $m$  increases. But it does not provide a clear solution to the basic problem being investigated. The length of the period of maximum homogeneity,  $h$ , apparently depends entirely on the particular record for which it is computed. Changing the number of observations,  $n$ , by a single year can result in a drastic change in  $h$ . It is no more constant than any other basic or derived aspect of climate.

The number of years,  $k_{1,1}^*$ , for which the mean is closest to the next year's value has been determined, in previous Reports, for the specific periods over which the elements were studied at two dozen stations around the world. The length,  $n$ , of these periods ranged from 57 years for sunshine percentage at 9 stations to 206 years for temperature at Basel (SR 4).

For these periods, elements, months, and stations, values of  $k_{1,1}^*$  vary generally from less than 10 to more than 50 years. But  $k_{1,1}^*$  can change markedly if a different, shorter, or longer period of years,  $n$ , is used, and certainly changes from month to month and element to element. No valid average

value can be obtained for  $k_{1,1}^*$ . Furthermore for prediction  $m$  years ahead, as shown in previous Sections of this Report, generally  $k_{m,1}^* = k_{1,1}^* - m$ . Since a climatic average is used to estimate not only next year's value but values two or more years ahead, a climatic "normal" should be based on some average  $k^*$ , perhaps that for  $m = 5$ .

Although no average best value for such a  $k^*$  can be established, the variations in  $k_{1,1}^*$  show that, on the whole, for all elements at all stations in all months, prediction one year ahead is just as good from an antecedent 10 or 15 year mean as from one based on a longer period. Because many stations have short records, the number of stations for which normals can be computed will increase with a decrease in the length of the period on which the normal is to be based.

The obvious conclusion of this study, therefore, is that 30 years is far too long to form the basis for a useful climatic normal. Instead, normals should be based on no more than 15 years, and recomputed every five years.

Routine collection, computation, and publication of such values would require two or three years, so that their general use would be for prediction three to eight years beyond the end of the averaging period. For such use these "normals" would be, on the whole, closer to the values which will actually occur than would be the present 30-year normals, from which departures are zealously computed and analyzed, often with consternation.

Even better than 15-year averages would be the medians of 15-year values, as amply demonstrated by William Slusser in SR 3. Medians are somewhat better than means for predicting elements with symmetrical distributions, such as temperature, in which theoretically mean and median coincide. They are far better than means for elements with skewed distributions, such as precipitation and windspeed. Despite long agitation, however, conservative climatology may not yet be ready to abandon the inefficient mean in favor of the simple median.

Finally, these considerations require reassessment of other climatic computational concepts, and indeed of the basic definition of climate. Many climatic problems require only

one value per year, rather than means or medians. Extreme value analysis, to determine return periods, is not considered valid unless based on at least 30 years. If climate is as inherently nonstationary as is indicated by the present investigation, how valid are these estimates?

Climate itself, once considered to be constant and now defined in terms of some time interval, often taken as 30 to 50 years, may require closer definition. Apparently it changes even during 30 years, and so no more than 15 years are recommended here for computation of normals. Even this may be too long for a basic definition, yet "climate" means something more than the conditions during a single year, or even two. Perhaps the alternation of seven years of plenteousness and seven years of dearth, which afflicted Egypt just as Joseph had foretold from the Pharaoh's dream (Genesis 41), is characteristic: seven years may be a suitable period for defining climate, and even for normals.

## 7. Acknowledgements

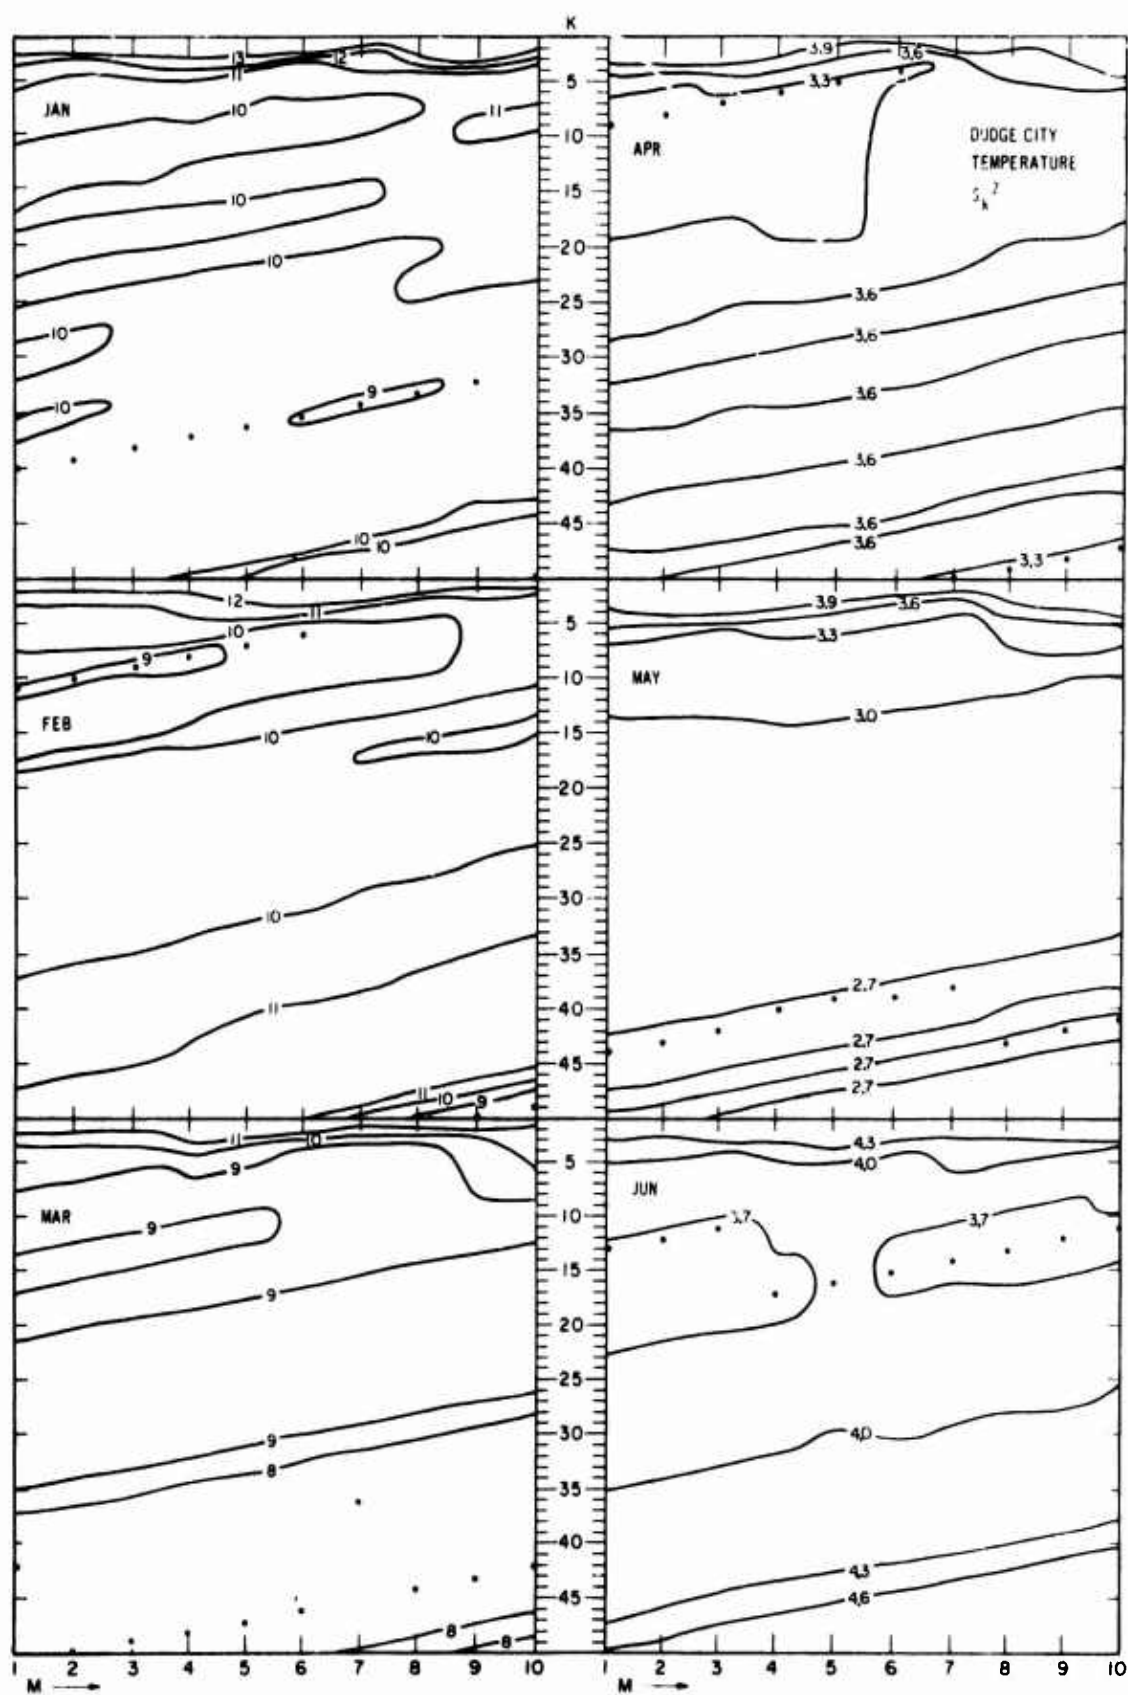

Most of the tedious labor for this study was done or directed by William Slusser, whose master's thesis forms SR 3. He revised and extended the basic computer program, introducing many useful innovations. He helped design and execute the various graphic presentations, and supervised their drafting by an assortment of graduate students. One of them, Ward Koutnik, used some data tabulations, assembled at the outset of the investigation but found to be unsuited for the analysis procedure eventually adopted, in his master's thesis, of which a summary has been published: "Newhall Winds of the San Fernando Valley," *Weatherwise* 21 : 186 - 189, 202 (Oct. 1968).

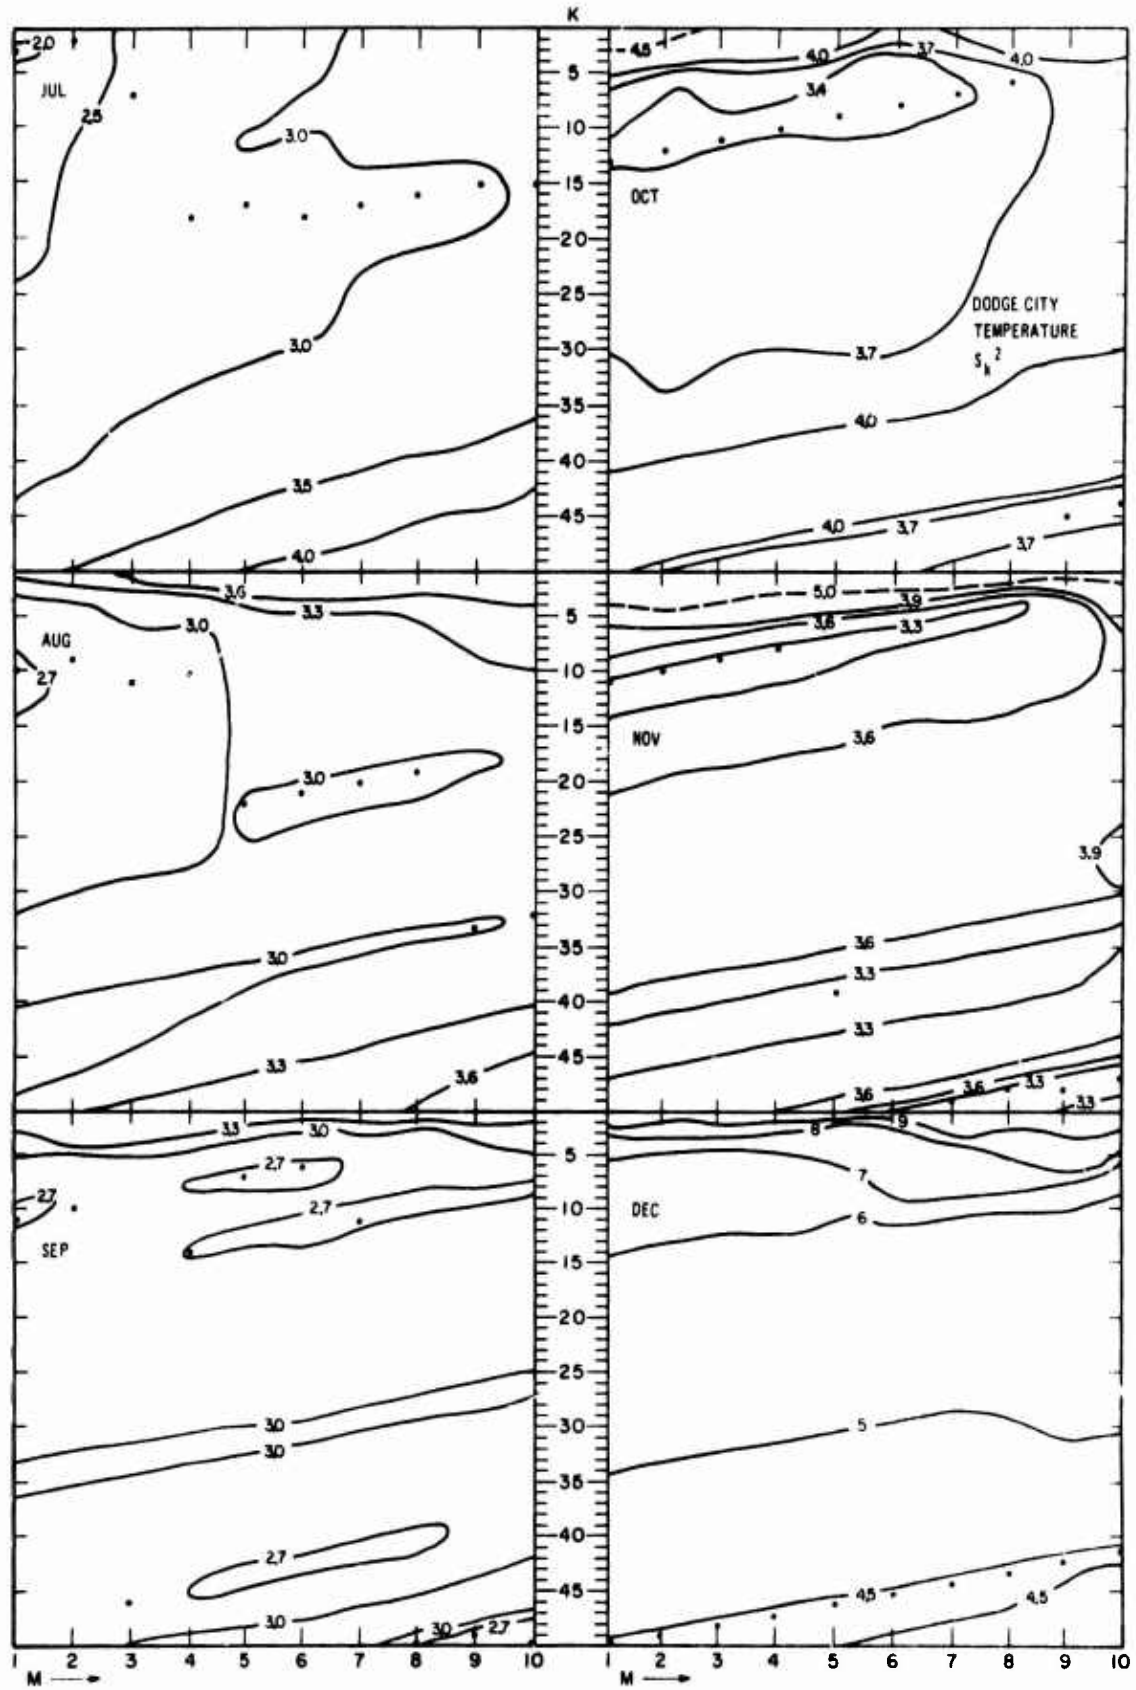

Probabilistic models of climate elements (mentioned in Section 4) were investigated in detail, with the assistance of Dr. Alfredo Baños, assistant professor of mathematics at San Fernando Valley State College and a consultant to the project. Non-linear decrease of serial correlation, with increasing lag, was studied extensively, but without useful results. Dr. Baños also aided in the interpretation of the statistical

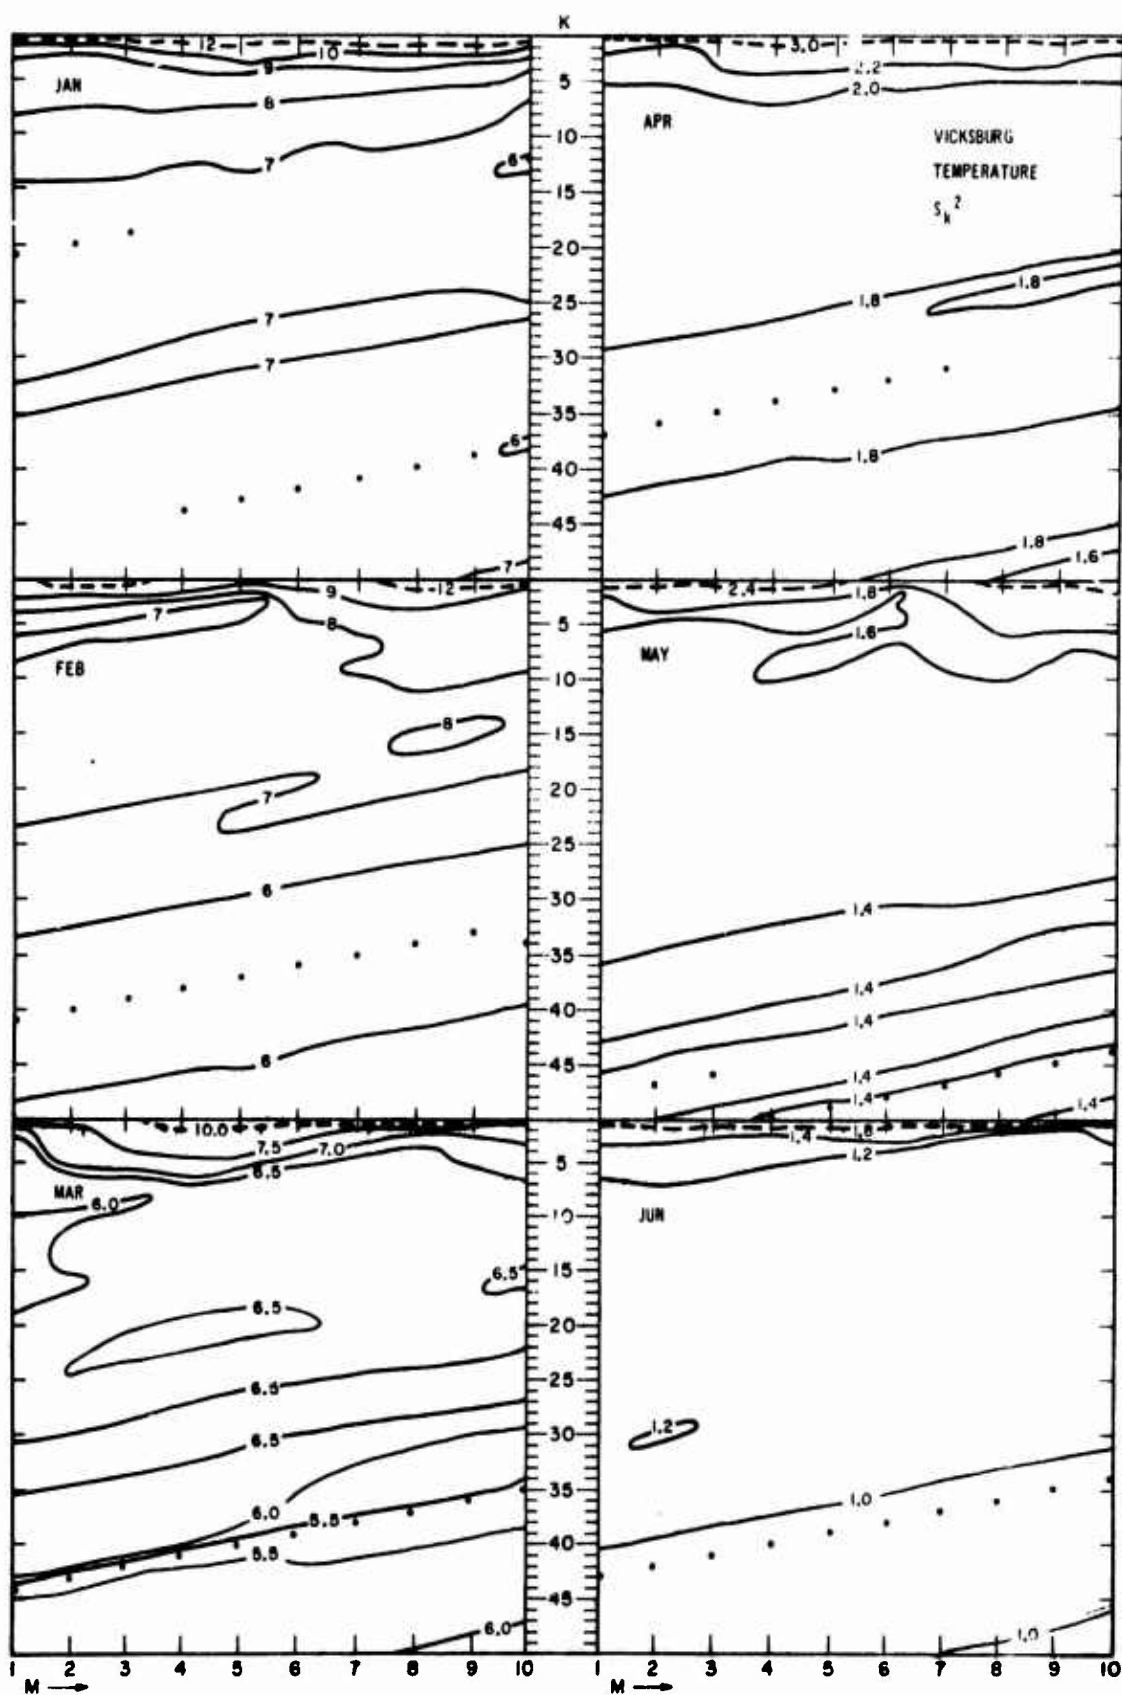

procedures reported by Rubinshtein in the second of the two Appendix papers, both of which were translated by Mr. George S. Mitchell, also a consultant.

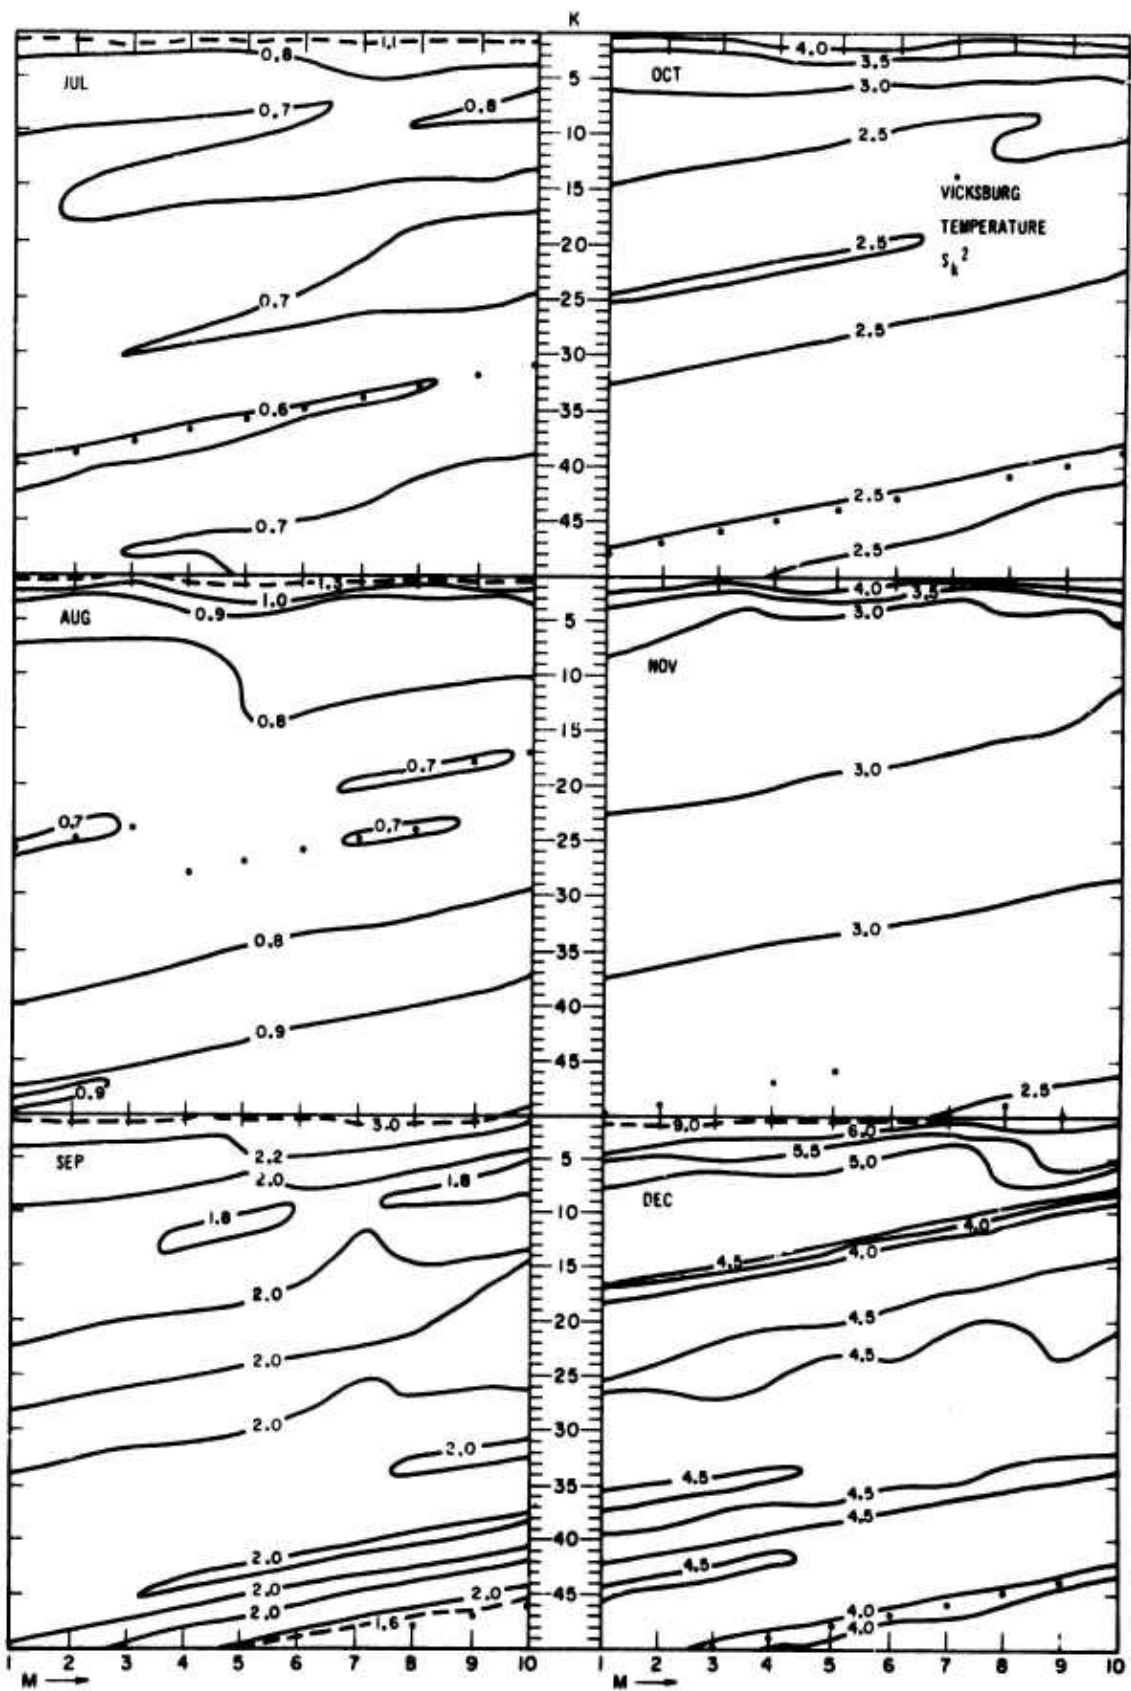

As unexpected results were developed in the course of the investigation, the principal investigator sought opportunities to discuss them with colleagues around the country. To this end, seminars were offered at the Air Force Cambridge Research Laboratories, the University of Oklahoma, the Weather Bureau's Central Regional Headquarters in Kansas City, the University of California at Los Angeles, and the Santa Barbara-Ventura chapter of the American Meteorological Society. A paper entitled "Climatic Normals are Inefficient" was presented at the A.M.S. Conference and Workshop on Applied Climatology in Asheville, N.C., on 31 October 1968. Some of the material of that paper has been used in this Report, which also has benefited from discussions with colleagues, too numerous to mention, at Asheville and elsewhere.

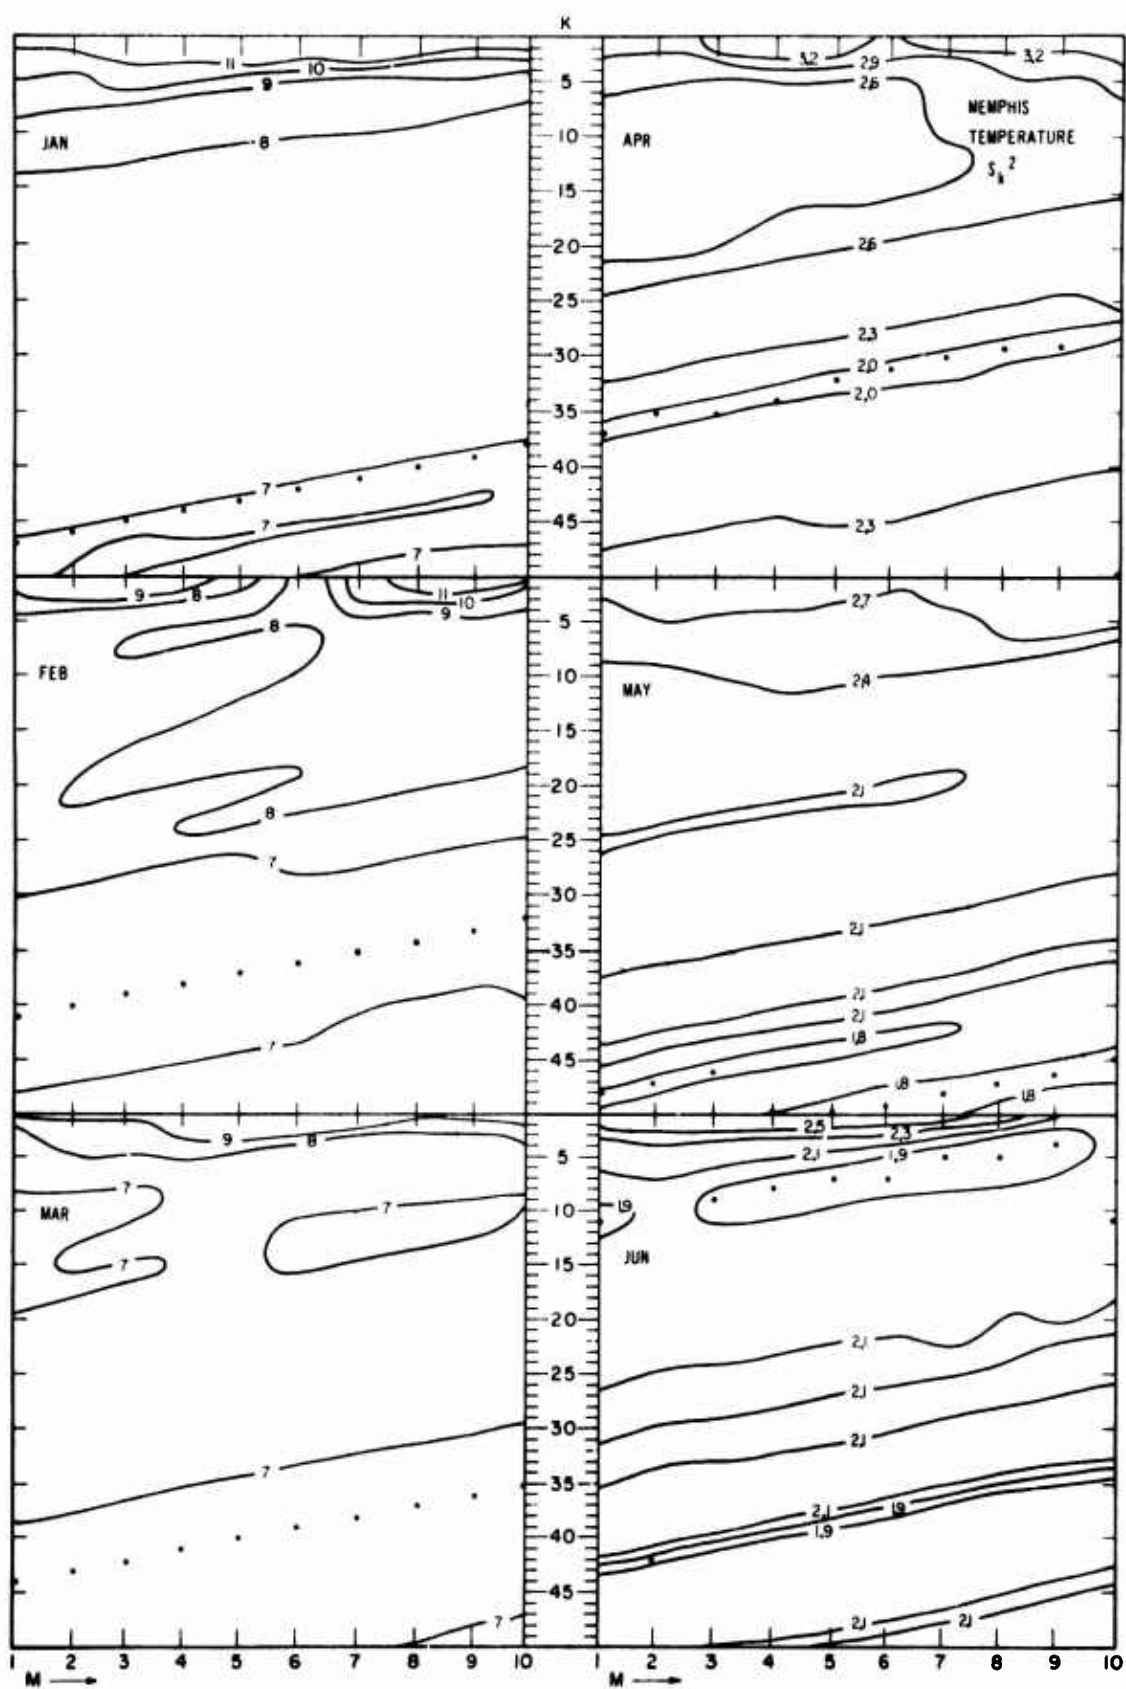

Figures 5 through 18 present, by isopleths,  $S_{k/m}^2$  for  $\lambda = 1$  as a function of  $k$  and  $m$ , for monthly temperature and precipitation at 7 U.S. stations, already studied in detail in SR 2. The charts have been discussed in Section 3.

# THE OPTIMAL LENGTH OF PERIOD FOR CLIMATIC AVERAGES

by O. A. DROZDOV, V. V. ORLOV, and TS. A. SHVER.

**Abstract:** For the pressing problem of selecting the length of period for climatic averaging, a new empirical method of verifying the degree of stability of climatic series is proposed, exemplified by observational series on air temperature and atmospheric precipitation.

## 1. Problem

The optimal length of series to be averaged in climatological processing has not yet been determined. Some climatologists advocate the longest possible series for which the stipulation of comparability in time and space is maintained [1, 2, 3]. Others recommend relatively shorter periods, for reasons limited primarily to technical aspects, for example to the assumption that the actual accuracy of the observations is small and is attained with a comparatively short length of observations.

On the other hand, more rigorous procedures, especially the method of sequential analysis, both in the USSR and abroad, [6, 10], point out the need for much longer periods, of the order of 70 years, to assure a much greater stability of the averaging. This is natural because the coherence of meteorological series, as a rule, results in smaller variance than in a series made up of purely random terms.

Other approaches to this problem have also been taken, both in the USSR and abroad. Abroad, [6, 9], to extrapolate values for the next year or two, a 15 to 20 year period was found optimal.

## 2. Russian Findings.

In the USSR this problem has been posed in a more general form: extrapolating means to the next 15 to 20 years, or at 5-year intervals beyond the period of averaging. A major consideration is that 5 to 10 years are required for processing the original data and publishing them (in the past up to 20 years have been spent) and each tabulation is used for more than 10 years.

Concerning precipitation, Sharov and Shver [3] showed that the improvement in accuracy from lengthening the period is small, but 50-year averages offer better extrapolation than averages of shorter series.

From temperature data of 9 stations (Leningrad, Salekhd, Yeniseysk, Yakutsk, Barnaul, Nerchinskii Zavod, Vladivostok, Tbilisi, Kazalinsk) for January, February, April, July and October, V. V. Orlov has found that monthly temperatures, averaged for 10 years, usually showed smaller differences from preceding 50-year averages than from preceding 10- or 25-year averages. Only half as often were the differences larger than for the shorter antecedent periods. For the 9 stations, the divergence between the average temperatures for 25 and 50 years and the subsequent 5, 10 and 15 years is 0.1 deg less than for 10-year averages, and during winter the decrease reaches even 0.3 deg (Table 2).

Significantly, a substantial increase in accuracy from using a 50-year average temperature is obtained even for January, when the secular variation of temperature is most sharply expressed. Obviously, this is associated with the large aperiodic random fluctuations of air temperature from year to year during this month. Only in April, when the variability of the temperature from year to year is smallest, does the extrapolation of the mean appear to be more accurate when computed from a shorter antecedent period (on the order of 30 years).

### 3. Varying Criteria

The average for 30-year periods, which are the basis of the climatic norms of the World Meteorological Organization (1901-1930 and 1931-1960), however, are without scientific foundation. In extrapolating a norm, the optimal length of the averaging period depends on the length of the period for which the extrapolation is made, and may vary depending on the purpose for which the mean is used.

The period used to describe climatic characteristics for practical purposes must vary with each objective, as for example, for biological purposes [Davitaya]. To investigate field crops, data for specific years may be required; to determine natural vegetation, periods of an order of decades or even centuries must be considered; to study the formation of soils the climate over many centuries or even millenia must be taken into account. Here, too, not only the averages but also other climatic characteristics are needed.

The various objectives cited by Davitaya involve extremely different periods of time, hence the requirements for the descriptive climatic norms must vary substantially. Obviously, requirements must differ even in designing industrial products intended for different lengths of service. Consequently, no single optimal period of averaging can be suitable in all fields, unless the average of a series of meteorological values tends toward some kind of limit as the averaging period increases. Whether such a limit exists, in principle, is not altogether clear.

Thus for periods so long that the composition and properties of the atmosphere may change substantially--the geographic, astronomical and astrophysical conditions of the geological past--constancy of climate at a given place on the earth's surface cannot be assumed, although certain astronomical factors vary quasi-periodically. Even over shorter periods, since the end of the latest glaciation, important changes occurred in climate in which, of course, some rhythmic oscillations of varying length prevailed.

In addition, consideration must be given to any absolutely aperiodic variation whose origin has not been established. In the assumed cyclical oscillations of a tidal character [9], as well as those of astrophysical and of auto-oscillatory character in the atmosphere-hydrosphere system (continental and sea ice), the average lengths of complete cycles are of varying order (1850 years, hundreds of years, several hundreds of years, 11, 8,  $5\frac{1}{2}$ , 2 years, and others less substantiated). Consequently, the stability of climatic norms over a long period is doubtful, inasmuch as the variations of a climatic regime are not only multicyclic but obviously cannot be reduced entirely to cyclic recurrence: in general, any series of climatic indices will be divergent.

#### 4. Estimating Stability.

The degree of stability of a climatic series may be verified empirically. The theory of series with damping constraints [4] assumes that the process of averaging excludes short cycles, and thus increases the stability of the averages. Moreover, if a climatic series diverges, then any increase in the period of averaging beyond a specific length not only does not increase the stability, but conversely will contribute to the recession of the averages from present-day conditions.

The insufficient length of instrumental observations does not permit distinguishing an overextended cycle from an irreversible change in climate. The limited development of the theory of climatic oscillations does not provide a solution of this problem by taking into account general regularities; it must be approached empirically by comparing the variabilities with a different averaging [6].

Of the different variants of such an approach, of interest here is the successive averaging for various long periods beginning with the most recent year. Use of such a series is rather natural because climatologists, for a number of reasons, tend to use observations up to recent years; the years thereafter will be considered subsequent, except for periods of interruption in the observations. The question, "What year completes the period of the averaging?" always arises.

By investigating the damping of oscillations of averages for successively increasing periods, the following problems may be solved:

1. Whether an average tends to any type of limit, or, at least for the period of observations available at our disposal and beginning with such a number of years of observations, whether the average becomes practically constant and does not depend on the length of the period.
2. whether the averages show symptomatic variations. If the meteorological homogeneity of the series has been established, such a variation may indicate (a) the presence of "ultrasecular" (more than 100 years--Tr.) oscillations with a period equalling the very large actual number of years of observations, or

(b) a change in the meteorological regime at the station as the result of an unobserved inhomogeneity, or (c) an actual rapid change in the meteorological regime in a given region (for example, the creation of a new reservoir or the drying up of a lake like the Caspian Sea).

## 5. Results

To examine the problem, monthly temperature and precipitation data, each for six stations, were studied: temperature for January, April, July and October, and precipitation for the warmer (April-October) and colder (November-March) seasons, and also for individual months (five stations for January and July; one station for August and April). Results are summarized in Tables 3 and 4, and given in detail in the Appendix. [Omitted]

In most cases, the mean temperature became relatively constant as the series was lengthened, and was independent of the period. The latter result was obtained when the series became longer than 50 and sometimes only when longer than 80 years. In certain cases a further lengthening of a temperature series is useless, because the temperature gradually diverges from values characteristic for present-day epochs. Such, for example, are the results of averaging January and April temperatures.

Dry years at the beginning of the second quarter of the 19th century are strongly reflected in the average value, even when computed for years including recent years of the 20th century. This is especially characteristic for Barnaul and Leningrad, for which series are long enough to investigate the dry period. How frequently such long dry periods develop has not yet been determined, and whether they consequently must be considered is not now clear.

Table 1. Number of cases, by months, in which increasing the period of averaging decreased (-), increased (+), or did not change (0) the difference between that average and that for the following ten years.

Month	50 years vs. 10 years			50 years vs. 25 years		
	-	+	0	-	+	0
JAN	8	1	0	6	1	2
FEB	8	0	1	6	1	2
APR	4	4	1	1	5	3
JUL	4	2	3	2	3	4
OCT	5	2	2	5	4	0
J+F+0	29	9	7	20	14	11
TOTAL	21	3	3	17	6	4

Table 2. Average difference between mean temperature for 10, 25, and 50-year periods and mean temperatures of following 5, 10 and 15 year-periods.

Month	for next 5 yrs			for next 10 yrs			for next 15 yrs		
	10	25	50	10	25	50	10	25	50
JAN+FEB	1,4	1,1	1,1	1,2	1,1	1,1	1,2	1,0	1,0
MARCH	1,4	1,4	1,4	1,4	1,4	1,4	1,4	1,4	1,4
JULY	1,3	1,3	1,1	1,3	1,3	1,2	1,3	1,3	1,2
OCT	1,3	1,3	1,3	1,3	1,3	1,3	1,3	1,3	1,3
TOTAL	2,1	2,1	2,0	2,1	2,0	2,0	2,1	2,0	2,0

In this study, the optimal averaging period to yield the best stability of the monthly averages, especially for temperature, was found to be of the order of 50-80 years, beginning with recent years. For precipitation, the length of the series is the same, although as yet how to handle the pronounced negative precipitation anomalies during the 1830's and 1840's is not clear. If this phenomenon is cyclic in character, the optimal length must be increased to 150 years or even more. If similar anomalies are extremely rare, the period of averaging might be less than 150 years but not including the anomalous years.

The lack of sufficiently long series of instrumental observations prevents solution of the problem as stated originally. Clearly the existing series of observations of precipitation amounts are not long enough for their averages to achieve stability; attempts of some authors [5] to estimate precipitation normals by extending shorter series are without firm foundation.

## THE PROBLEM OF AVERAGING PERIOD IN CLIMATOLOGY, BY E. S. RUBINSHTEIN

ABSTRACT: The problem of length of period required for obtaining consistent climatic mean values is examined. The change in climate occurring over a greater part of the world renders the 30-year period to have no scientific basis.

### 1. Introduction

The length of period to be used in computing climatic averages is a problem that has long awaited solution.

The great lack of comparability between similar studies covering just one country, as well as between studies of different countries, impedes the development of climatic theory and the solution of practical problems.

This problem should be solved formally on an international scale, but at each of the three sessions of the [W. M. O.] Climatology Commission, at numerous conferences of regional organizations, in working groups, and in a number of periodicals published in different countries, the solution usually adopted has been subject to criticism. Its practical use frequently gives unsatisfactory results, because the 30-year period for averaging climatic values has insufficient scientific basis.

Undoubtedly, the problem of what period must be selected as "standard" for computing climatic "norms" for the entire world has many difficulties, but they are surmountable and a reasonable answer can be found. The difficulties arise from the differences in climates in various parts of the world, and from the variety of purposes for which many-year averages are computed.

Climates in the USSR vary from the Arctic in the north to subtropic in the south, from marine along sea coasts to severely continental in the interior, and from plains to high mountains. The density of the network of meteorological stations, and the length of the series of observations, differ in different parts of the USSR.

For these reasons, Soviet climatologists have become increasingly more interested in the problem of the most rational selection of a period to yield stable and mutually comparable average values of the meteorological elements. In addition, Soviet scientists have dealt with the entire world and the Northern Hemisphere. All these works have provided extensive experience in methods of climatological processing of observations over the entire world--and in particular on the problem of the most rational selection of the period for obtaining stable average values of the meteorological elements. The following considerations are inferences from this experience.

## 2. Requirements

Many-year averages of meteorological elements are used for the most diverse purposes, but all may be divided into two categories.

In some cases, the absolute values of the meteorological elements are not so important as the differences or relations between them at individual stations, or over individual portions of the area under study. Thus, for example, questions arise concerning differences in air temperature between city and surrounding areas, between coastal and interior stations, and between valley and slope stations. To solve such problems, a long period of observations is not required, but during too short a record, the relations may not be the same in different seasons or under different types of atmospheric circulation. A 10-year period has been found sufficient provided the series is homogeneous.

In another category of problems, great absolute accuracy of the average average values of the meteorological elements has been found essential through extensive contact between climatologists and specialists in pertinent branches of science and practical work. These problems include designing modern grandiose constructions (dams, canals), predicting long-period levels of enclosed seas and lakes, establishing the connection between climate and landscape (relief), investigating climatic changes, et cetera.

How can one scientifically determine the length of a series necessary for obtaining stable averages of climatic elements? The very nature of the fields of different meteorological elements precludes stability in time (from year to year). Therefore, the length of the series which will assure stable mean values is not the same for different elements.

In addition, climatic changes in one form or another, embracing the entire world, are now well-known. These changes complicate the problem and its solution even more--rational selections of the period for which climatic averages must be computed will differ, depending on whether these variations are rhythmic (oscillations) or tend in one direction (rise in air temperature, decrease in precipitation amount, etc.)

### 3. Temperatures

The problem of the observational period necessary for obtaining stable average monthly air temperatures will be discussed first. Numerous works of scientists in many countries have defined the nature of air temperature variations with time, and the regions in which they occur. The vast amount of material on the problem of temperature change published in recent years [1, 2] is too well known to require discussion here. These data provide the objective basis for a further consideration of the problem of the period necessary for obtaining stable averages.

The magnitude of the differences between temperatures in individual 10-year periods is shown by the following examples. At Salekhard the average temperature for November, 1885-1894, was -19.2 C but for 1934-1943 it was -10.5 C; the southern regions of the USSR differ only a little from this. At Kazalinsk the average January temperature, 1886-1895, was -14.8 C but during 1909-1918 only -7.9 C. At Barnaul during the 1940s temperatures on the average were 5 deg higher than at the end of the 19th century.

Such differences sometimes are attributed to the growth of cities, but a number of works both by Soviet and foreign scientists show that this is not the chief cause of the instability in 10-year averages. This follows from analysis of individual months (adjacent months should show analogous increases in averages) and also from comparison of moving averages for corresponding months at neighboring stations, one urban, one rural. Nowhere have temperatures in the city and in nearby open locations been found to be so large.

The well established changes in temperature with time has led to the conclusion that the mean monthly temperatures over a 30-year period are unstable. For corroboration, Table 1 presents the differences between average monthly temperatures for two 30-year periods, 1931-1960 and 1901-1930, at 7 stations in different portions of the USSR.

---

TABLE 1. DIFFERENCES BETWEEN MEAN MONTHLY TEMPERATURES,  
1931-1960 and 1901-1930

---

	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	OCT	NOV	DEC
Leningrad	-0.3	-0.3	-0.6	0.1	0.1	0.7	0.6	1.3	0.5	0.6	0.4	1.0
Kiev	-0.8	0.0	-0.6	0.1	0.3	0.8	1.3	1.2	0.9	0.1	0.2	0.4
Sverdlovsk	0.7	0.3	-0.3	0.6	0.7	0.6	0.5	1.1	0.4	1.0	-0.9	0.5
Salekhard	2.3	-0.5	-0.1	1.9	1.4	0.9	0.1	0.4	0.3	0.9	2.0	0.2
Turukhansk	1.6	1.0	0.6	2.0	1.2	1.4	-0.1	-0.5	0.7	1.0	-0.8	2.5
Kazalinsk	-1.2	0.8	0.3	0.7	-0.2	-0.4	-0.6	0.0	0.4	0.2	-1.3	-0.6
Barnaul	-0.7	-0.4	0.6	1.3	0.2	0.1	0.2	0.1	0.3	1.4	-1.9	-1.2

At each station in some months the differences between temperatures in the consecutive 30-year periods exceed 1 degree and some are around 2 degrees (Salekhard in January, April and November; Turukhansk in April and December; Barnaul in November). In most months the period 1931-1960 was warmer than the 1901-1930 period, but in certain regions cooling appeared in winter (Leningrad, Kiev, Kazalinsk, Barnaul).

A change in sign of the differences during adjacent months results from a change in the character of the annual march of temperature during the second 30-year period compared with the first; sometimes the month with the lowest temperature changed. Thus, during 1901-1930 at Salekhard the January and February temperatures are -24.4 C and -21.8 C respectively and during 1931-1960 -22.1 C and -22.3 C. January and February temperatures at Kazalinsk were identical during the first period (-10.0 C), but were -11.3 C and -9.1 C in 1931-1960.

Thus, at Salekhard the January and February temperatures were characteristic of a continental climate during 1901-1930, but of a marine climate in 1931-1960; at Kazalinsk the relation was reversed. At Barnaul the drop in temperature from October to November during 1901-1930 was 8.8 deg. but during 1931-1960 it was 12.1 deg.

#### 4. Inadequacy of 30-year Period

Clearly, a 30-year series of observations cannot yield stable average monthly temperatures in the temperate zone, and especially in the polar zone where the change in climate is great. A 30-year period cannot be used as the "standard" for comparison. With which of the two 30-year series should temperatures of current years be compared to provide departures from the "norm"? At first glance, the second period seems more natural, but no scientific basis exists for this choice.

Many scientists believe that the warming period has ended and a cooling has begun. Actually the nature of a climatic change is much more complex; in some regions the warming continues while in others it has terminated. This is very evident from the variation of the moving averages presented by Polozova and Rubinshtein [2]. It also is evident from Table 1, which shows, for example, the oscillations in temperature at Salekhard and at Kazalinsk to be in opposite phase in January, February and November.

In addition, even where the 1931-1960 temperatures are, on the average, higher than during 1901-1930, sharp differences may be observed between monthly temperatures of consecutive years in both periods. For example, the January temperature at Leningrad in 1925 was -0.5 C while in 1926 it was -12.9 C; in 1929 it was -10.3 C but in 1930 only -0.9 C; in 1949 it was -2.2 C while in 1950 it was -13.9 C; the December temperature was -1.3 C in 1954 but -14.0 C in 1955. In a region with very pronounced warming, temperatures from one year to the next may vary greatly; for example, the mean April temperature at Salekhard was -4.5 C in 1955 but -14.5 C in 1956.

Another inconsistency arises in using 30-year periods, 1901-1930 or 1931-1960, as standards. In many countries, including the USSR, maps have been constructed of the departures of temperatures from the many-years average for each month of the year. These maps are widely used in scientific work, and also considered by synoptic meteorologists in search of analogs. Departures from the many-year averages are published also in "Monthly Climatic Data for the World".

, Prior to 1960, the standard period was 1901-1930, but beginning in 1961 the 1931-1960 period has been used. If, for example, at some station the January temperatures were identical in 1960 and 1961, use of different "norms" caused departures from normal to be different, and sometimes even of opposite sign.

### 5. Deficiencies of Short Periods

Use of means for a recent brief period is defended by some writers on the assumption that temperatures of the most recent years will be closer to the 30-year period just ended; this hypothesis has no scientific foundation. Examples presented previously show large differences in the monthly temperatures from one year to the next.

Other advocates of short series of observations cite the conclusions of Beaumont [5] and Enger [6]; these works offer an obvious ambiguity. As is evident from the very title of the work, Beaumont used moving averages to select objectively the period for averaging precipitation amounts to predict for the subsequent year. Analogous work for air temperature led Enger to the conclusion that moving averages for 15 up to 20 years are most suitable for predicting temperature during the subsequent years. But moving averages cannot be used as a "standard", either for a climatic atlas or as a "norm" for calculating departures for individual years.

Steinhauser [7] also pointed out the unsuitability of the 30-year means as a "standard". Absolutely correctly, he asserted that certain 30-year means vary so that they may be used better as indices of climatic fluctuation rather than as the bases for climatic maps. The same result is shown in Mitchell's report at the Rome symposium in October 1961, comparing means for the two 30-year periods, 1891-1920 and 1921-1950.

### 6. Advantages of 50 to 80 Years

How can a rational conclusion be reached from the assumptions that have been made? The 10-year moving averages of monthly temperatures show an oscillatory character in the change of temperature; evidently several rhythms are superposed over each other, and consequently the distances between corresponding phases of the resultant curve are variable. The most stable monthly average temperatures can be obtained only from a very long series of observations.

Addition of the last 25 years to the 55-year mean 1881-1935 (Table 2) in most cases changes the many-years' average only by 0.1 to 0.3 deg., but in regions of more pronounced climatic change the many-year average temperature during certain months varied even as much as 0.8 to 1.0 deg. (Salekhard, April, June and November).

Thus, the average monthly temperature for a period of 50 to 80 years may be taken as the "standard" with which to compare data for individual years. Only such averages are suitable for constructing climatic maps, although for individual regions with a pronounced climatic change even these long-period averages may be insufficiently stable in individual months. Only climatic data obtained from long periods of observations should be considered in constructing huge projects designed for a prolonged existence (dams, canals, et cetera).

#### 7. Extrapolations of Short Series

However, stations with a long and also homogenous series of observation are too few to provide climatic data for research and practical purposes. In the opinion of some, this is the chief obstacle to using the 50-80 year averages as the "norm". This objection would be valid if calculation of the many-years averages were restricted to simple arithmetical computation. But modern climatology has developed a theory of extending short series of observations to a long period, by differences for air temperature and humidity, by ratio for precipitation.

The method of extending short series of observations to a long period has been widely applied for many years by Soviet climatologists, for studies of the Soviet Union and of other countries. Undoubtedly, the long periods to which data of individual countries will be reduced cannot be identical over the entire world. Nevertheless, means for 50 to 80 year periods will be more comparable with each other than averages for a common but brief period, as Drozdov [3], has demonstrated.

(Editor's Note: The following discussion has been translated faithfully, with slight changes in notation--from  $n$  and  $N$  to  $m$  and  $n$ , and with subscripts rather than superscripts in parentheses. However, the basic inconsistencies in the original presentation cannot be removed, and the original paper [3] is unavailable. Apparently the quantities in Eq. (1) are not actual variances, but estimates of precision; Eq. (2) cannot be derived by standard statistical methods, so the validity of the result is not established.)

Data for two stations,  $X$  and  $Y$ , for  $n$  and  $m < n$  years, respectively, are considered. The variance of the difference between the  $m$ -year averages at each of the two stations may be compared with the variance of the difference between the  $n$ -year average at  $X$  and the  $m$ -year average at  $Y$ . If the first variance is less than the second, data for the two stations can be compared more adequately from the two  $m$ -year series than by using  $n$  years at  $X$  and  $m$  years at  $Y$ :

$$\sigma^2 (\bar{x}_m - \bar{y}_m) < \sigma^2 (\bar{x}_m - \bar{y}_n), \quad (1)$$

where  $\bar{x}_m$  and  $\bar{y}_m$  are the average values of the meteorological element in question at stations  $X$  and  $Y$  for the  $m$  years, and  $\bar{x}_n$  the average for the entire  $n$  years. This condition may be rewritten in terms of  $r_m$ , the correlation coefficient between temperatures at stations  $X$  and  $Y$  during the  $m$  years, and of  $\sigma_x^2$  and  $\sigma_y^2$ , the corresponding standard deviations, as

$$\frac{1}{m} \sigma_x^2 + \frac{1}{m} \sigma_y^2 - \frac{2}{m} \sigma_x \sigma_y r_m < \frac{1}{n} \sigma_x^2 + \frac{1}{m} \sigma_y^2 - 2r_m \sqrt{\frac{m}{n}} \sigma_x \sigma_y / \sqrt{mn} \quad (2)$$

Hence  $r_m > \sigma_x / 2 \sigma_y$  is the condition under which extension of a short series of observations to a longer period by the difference method gives a more accurate value than one computed directly. Thus, at distances between stations at which extension to a long series is impossible, a long series of observations is more comparable to a shorter one than would be two short synchronous series.

Extension of a short series to a long period improves the accuracy of the many-year average value when the correlation between temperatures at the stations under comparison satisfies

$$r(x,y) > \sigma_x / 2 \sigma_y \quad (3)$$

When  $\sigma_x = \sigma_y$ , which often occurs in lowland areas, the condition for the feasibility of extrapolation becomes  $r(x,y) > 0.5$ . Isocorrelation lines [1], [4] indicate  $r = 0.5$  at distances of hundreds of kilometers between stations, depending on season. If  $\sigma_x \neq \sigma_y$ , which occurs in comparing coastal with continental stations, or mountain with plains stations, etc., the critical value of  $r$  depends strongly on the ratio  $\sigma_x / \sigma_y$ .

The above discussion shows that computation of the average monthly and annual temperatures for long but not identical periods in different countries is entirely possible. Such data will be more comparable with each other and more stable than those for synchronous but shorter periods.

## 8. Other Elements

For further comparison of "norms" for different periods and for other meteorological elements, the conclusions obtained from study of the actual data will be discussed only briefly. The principles on which the conclusions are based are the same as for many-year averages of air temperature.

Atmospheric pressure for individual 10-year periods in the USSR may vary greatly: by as much as 1.3 mb at Leningrad in February, for example, and by 4 to 5 mb at Barnaul and Kazalinsk in January. Differences between atmospheric pressure in November 1931-1960 and 1901-1930 at Leningrad, Moscow and Sverdlovsk are at least 4 mb (Table 3). Large pressure differences are observed also in other months (Leningrad: August; Barnaul: January; Sverdlovsk: January, February, June). The inadequacy of a 30-year period for providing stable averages of pressure is perfectly obvious. Extrapolation of a short series of observations to a long period improves the accuracy of the average monthly pressure values in the temperate zone, even over distances of the order of 500 km. An obvious expedient is to use the same base period as for the air temperature.

Precipitation amounts show great variability with time (from year to year), as well as a rapid decrease in continuity of pattern between stations as the distance between them increases. Attaining stable monthly precipitation values is made much more difficult by the difference in instruments and exposures.

(1931-1960) / (1901-1930)

	APR	MAY	JUN	JUL	AUG	SEP	OCT
Leningrad	96	82	89	131	95	99	109
Kiev	95	101	84	87	111	94	119
Barnaul	119	104	110	123	103	94	77
Irkutsk	105	96	128	115	124	118	112

Monthly ratios of precipitation for two 30-year periods (Table 4) demonstrate the inadequacy of a 30-year period for obtaining stable mean values of the precipitation. At Leningrad the ratios vary from 82% in May to 131% in July; the annual march of precipitation is distorted from that obtained over a longer period. Similarly, the difference between ratios of precipitation amounts at two stations during different 30-year periods shows that the July value at Kiev was 148% of that at Leningrad during 1901-1930 but only 98% during 1931-1960, etc. (Table 5)

Although a 30-year period is inadequate for obtaining stable average precipitation values, recommendations are much more difficult than for air temperature and atmospheric pressure. Extrapolation of short series to a long period is possible, and actually is realized, but it is not feasible everywhere because of the rapid decrease in the correlation coefficient with dis-

TABLE 5. RATIOS (%) OF PRECIPITATION TOTALS AT PAIRS OF STATIONS FOR TWO PERIODS

		APR	MAY	JUN	JUL	AUG	SEP	OCT
Kiev/ Leningrad	(1901-1930)	135	108	126	148	79	80	82
	(1931-1960)	134	133	120	98	93	77	90
Irkutsk/Barnaul	(1901-1930)	66	84	136	136	143	99	34
	(1931-1960)	59	77	157	128	172	124	50

tance between stations. Nevertheless, extrapolation by ratios should be recommended because the results are more accurate than the non-reduced if

$$r_{xy} = (k/2) (\sigma_x / \sigma_y), \quad (1)$$

where  $k$  is the approximate selected coefficient. Average precipitation amounts must also be computed from possibly longer although non-synchronous averages.

Atmospheric humidity is characterized by small variations in time. In the USSR average values of absolute humidity computed for different 10-year periods may differ from each other by as much as 1 to 2 mb in summer, but by only 0.5 mb in winter. (Apparently this refers to vapor pressure, which is measured in millibars, and not to absolute humidity, which is measured in grams per cubic meter --Ed.) The 1300 hour relative humidity may differ by 5 to 10 percent, and the 24-hour average somewhat less, during different 10-year periods. Humidity data for 30 to 35 years are fairly stable; even in summer, absolute humidity (vapor pressure? -- Ed.) averages during different 30-year periods differ by around 0.5 mb, and average relative humidity at 1300 hours by 2 to 3 percent.

Reduction of short series of observations of vapor pressure to a longer period is feasible in lowland areas of the temperate zone for distances of 250 to 300 km and those of the relative humidity in summer up to 200 km. In winter the humidity is so stable from year to year that even a 20 to 25 year series yields satisfactory accuracy. These recommendations for obtaining a stable average for humidity are based on data for the Soviet Union; additional studies on this topic are required for other climatic zones.

### Conclusions

Analyses of series of meteorological observations of air temperature, atmospheric pressure, atmospheric precipitation, vapor pressure and relative humidity lead to the following recommendations:

1. In view of the great instability of average values of the meteorological elements (temperature, pressure, and precipitation) over a 30-year period, caused by variation in climate, neither 1901-1930 nor 1931-1960 should be assumed as standard on an international scale.
2. Average values of the meteorological elements which might be useful as "standards" for comparison of corresponding data, both in time and in different portions of the world, must be computed from long series of observations, on the scale of 50 to 80 years. These are not necessarily synchronous, because longer series are more comparable than shorter but synchronous series.

To compute such long-term averages the method of extrapolating short series of observations to a long period must be widely applied. The theory has been worked out in detail and verified in practice. In those few instances where such a reduction is not feasible (in countries with a poorly developed meteorological network), stations with longer periods, although still less than 50 years in length, should form the basis for extending shorter series at neighboring stations to a longer period. After some specified time (for example, 10 years) these means can be adjusted. Averages obtained in this manner may also be useful for constructing climatic charts and for computing departures from them for individual years, and for practical requirements generally.

To promote climatological studies pertaining to the entire world or the Northern Hemisphere, 10-year averages of air temperature and atmospheric pressure should be compiled and published, as well as maps of the distribution of these averages over the entire world. While such data may not be useful as "norms", they will be extremely valuable indices of the nature of the distribution of the meteorological element during the period, and of the extent and variation in its distribution from one 10-year period to another.

13. ABSTRACT		
<p>Methods of previous Reports, concerned with the number of antecedent years for which the mean value of a climatic element offers the minimum variance estimator of the next year's value, are extended to similar predictions more than one year ahead. For predicting a value <math>m</math> years beyond the end of the averaging period, the best average is found to be based on a period <math>m</math> years shorter than for predicting the next year's value. Apparently each climatic record has an average period of maximum homogeneity, whose length must be equalled, for optimum prediction, by the interval from the start of the averaging period to the end of the predicted one. Climatic normals for 15-year periods, rather than 30 years as at present, are recommended, with recomputation every 5 years. Medians of values over 15 years are suggested as even better predictors than means. Finally, 7 years is suggested as a suitable period for the definition of climate.</p>
